ABSTRACT
A novel algorithm has been developed for the non-destructive determination of the shape of the interface between a melt and a refractory material wall in smelter furnaces. This method uses measurements of temperature and heat flux at a number of points on the outer surface of the furnace and assumes that the inner (guessed) surface of the furnace wall is isothermal. The temperature field is then predicted in the entire furnace wall material by numerically solving a steady state heat conduction equation subject to the measured temperature values on the external surface and the isothermal melt material solidus temperature on the inner surface of the wall. The byproduct of this analysis is the computed heat flux on the external surface. The shape determination method then uses the difference between the measured and the computed heat fluxes on the outer surface of the furnace as a forcing function in an elastic membrane motion concept for the determination of the inner (melt-refractory) surface motion. The inverse determination of the melt-refractory interface shape can be achieved by utilizing this algorithm and any available analysis software for temperature field in the refractory wall. The initial guess of the wall inner shape can be significantly different from the final (unknown) wall shape. The entire wall shape determination procedure requires typically 5-15 temperature field analysis in the furnace wall material.

INTRODUCTION
Walls of the furnaces that contain molten material (metal, glass, etc.) are made of layers of bricks of high-temperature resistive refractory material. High thermal gradients inside the melt create very strong circulation of the melt that causes erosion of the inner wall surface of the furnace. This erosion could lead to the complete deletion of the protective refractory material at certain locations of the furnace wall. At such points, the molten material could easily soften the outer steel casing of the furnace and break it thus causing a major industrial disaster. Thus, it would be highly desirable to continuously monitor the actual thickness of the entire furnace wall so that the furnace can be shut down and the wall material repaired before the breakout happens. Use of any sensors imbedded in the inner surface of the wall (the melt-wall interface surface) is unacceptable, because the strong melt velocity field would wash such sensors away very quickly. One of the methods used in determination of the refractory wall thickness utilizes non-destructive measurement techniques and inverse shape determination.
concepts. Notice that this class of inverse problems is fundamentally different from inverse problems dealing with the determination of unknown boundary conditions on a known geometry [1, 2].

Shape inverse determination involves the ability to determine the shape of a configuration satisfying the governing field equation(s) subject to specified surface boundary conditions and certain geometric constraints. There is a multitude of shape inverse determination techniques that have been developed in various fields of science and engineering. Several research teams in countries with strong steel industries have been working on developing such non-destructive monitoring technologies.

Some of the pioneering work was performed in Japan by Yoshikawa et al. [3, 4], who considered axisymmetric configurations of blast furnaces. They attempted to incorporate the effects of the solidified melt layer in their inverse formulation based on the use of boundary elements method for heat conduction analysis and a shape optimization algorithm that could handle only a relatively small number of design variables.

Another significant effort in the development of inverse methods for determination of inner wall surface shape was performed in the ex-USSR (Ukraine) by a research team of Professor Matsenya [5-8]. They are concerned with the bottom of the flash smelting furnace which is the multi-layer structure consisting of refractory and heat-insulating materials. Two upper layers are built from chrome-magnesite brick and act as working and insulating lining. Underneath are the layers of refractory brick and light refractory brick, which are the heat insulators. The lower refractory brick layer lies on the concrete raft, which is cast on the horizontal steel plate that leans against the columnar concrete supports of the furnace foundation. The width of the wall domain in this problem is much larger than the wall thickness, it is practically symmetric relative to the transverse axis, and it has low heat conductivity of the component materials. These facts were used to justify the assumption of two-dimensionality of the temperature field in the furnace bottom wall. Apparently this team has not considered a simultaneous prediction of the inner surface of the furnace bottom and sidewalls.

Druckenthaner et al. [9] and Radmoser [10] in the Austria/Germany region of central Europe reported on a more mathematically involved method of simultaneously determining thickness of the bottom and the sidewall of the blast furnaces that involved the use of a regularization technique in order to prevent the ill-posed inverse problem from developing exponentially large errors. However, their approach did not appear to be flexible enough to treat realistic irregular inner wall surface configurations.

Sorli and Skaar [11] from Norway reported on a very exact and mathematically sound inverse methodology that converges quite rapidly because it utilizes an adjoint operator formulation. However, the method was demonstrated only for very simple smooth shapes of the inner surface of the wall that were not significantly different from the initially guessed wall surface configurations.

Professor Tanaka’s team [12, 13] utilized a sophisticated Kalman filtering technique and boundary element method to deal with axisymmetric configurations of the blast furnaces. Katamine, Azegami and Kojima [14], also from Japan, have developed a method based on the distributed sensitivity function that uses adjoint variables. Their approach is able to predict quite realistic shapes of the inner surface of the furnace walls, but does not seem to offer a consistently high accuracy in the prediction of the wall wear configuration.

None of the published work utilizing different inverse shape determination approaches has been demonstrated to work reliably when realistic values of temperature and heat flux measurement errors are included. In conclusion, despite the separate efforts of several independent research teams, reliable and affordable methodology for continuous sensing and monitoring of realistic three-dimensional variation of refractory wall thickness in smelters is still unavailable. What is available are several methods for the prediction of the furnace wall thickness variation in a two-dimensional horizontal or vertical plane assuming a perfect symmetry of the furnace inner and outer walls with respect to the vertical axis.

Furthermore, the existing methods do not offer simultaneously high accuracy, reliability and speed of the prediction of the wall thickness distribution. The objective of this paper is to elaborate on an alternative method for predicting reliably and accurately realistic two-dimensional furnace wall wear configurations. The new method [15] is based on the authors’ concept for inverse design of aerodynamics shapes [16-18] and could be conceptually extended to three dimensions.

GENERAL APPROACHES TO INVERSE DETERMINATION OF SHAPES

There exists a multitude of inverse techniques that are useful in solving different types of engineering problems. Two major classes of inverse tools for shape determination can be defined as methods with coupled field analysis and shape modification, and methods with uncoupled field analysis and shape modification. The coupled methods require an intimate understanding of the original field analysis code in order to make specific changes in the boundary condition enforcement subroutines. This is time-consuming and hard to accomplish if the original analysis code is not well documented and if the original developers are not available. When a designer uses a commercially available analysis code, he/she cannot perform its conversion to an inverse shape determination code since only a compiled version of the code is available.

The uncoupled inverse methods require no modification to a field analysis code. Thus, any reliable field analysis code or even experimental field measurements data can be used in the shape determination process without a need for alterations of such a field analysis tool. The field analysis code will be called during the inverse shape determination process as a large subroutine to compute boundary values of certain field variables. These boundary values will then be fed into the master inverse shape determination code that will compute new geometry updates. This means that even a compiled version of a commercially available field analysis code is perfectly acceptable since it only requires the updated geometry computed by the inverse shape determination master code. This
The entire procedure constitutes one iteration in the global inverse shape determination process. The uncoupled shape determination techniques have the added benefits of simplicity, relative ease of programming, and versatility.

Thermal Boundary Conditions

The essence of all inverse shape determination algorithms is that they require the boundary conditions for field problems to be over-specified on at least some portions of the known part of the boundary. In the problem of inverse determination of the inner surface of the refractory wall in smelters, this means that both temperature, $T_0$, and normal temperature derivatives, $\left(\frac{dT}{dn}\right)_0$ should be provided on the external surface of the refractory wall. A continuous reading of temperature $T_0$ on this surface can be accomplished by placing inexpensive and reliable temperature measuring probes on the outer surface of the furnace refractory wall. The normal derivatives of temperature on the outer surface of the refractory wall of a blast furnace could be measured inexpensively by placing another temperature probe a few centimeters radially inward from each of the outer surface temperature probes. The difference between the temperatures read by each probe in such a pair of temperature probes can be divided by the known distance between the two probes in a pair to provide the needed outer surface normal temperature gradient. Values of $T_0$ and $\left(\frac{dT}{dn}\right)_0$ are then interpolated at other surface points by using B-splines.

The inner surface of the refractory wall of the furnace is of an unknown shape, but the temperature of this surface, $T_1$, is assumed to be known and equal to the solidification temperature of the melt which is recirculating in the furnace. The assumption of isothermal solidus temperature on the unknown inner surface of the refractory wall is reasonable, although not exact, because there could be layers of solidified melt and slag on some parts of this surface. However, these details could possibly be resolved only by performing a highly accurate conjugate heat transfer analysis [19, 20] of the melt flow-field and the refractory wall. Such complex analysis capability is not available at the present time because of the stringent requirements on its high reliability, accuracy and speed of execution. Hence, the isothermal surface condition on the melt/wall interface is the widely accepted thermal boundary condition.

Elastic Membrane Concept for Shape Evolution

Inverse determination of the inner surface shape of the refractory wall of a blast furnace is based on the use of measured $T_0$ and $\left(\frac{dT}{dn}\right)_0$ (the over-specified boundary conditions) and on the postulated isothermal value of $T_1$. These boundary conditions are used in the following manner.

Garabedian and McFadden [21] first proposed the elastic membrane approach for inverse design of aerodynamic shapes where the body surface is treated as an elastic membrane that deforms under certain surface loads, $\Delta C_P(s)$, until it achieves a desired distribution of surface loads. The original non-physical model for the evolution of, for example, a two-dimensional aerodynamic shape was given by [21]

$$\beta_0\Delta n + \beta_1 \frac{d\Delta n}{ds} + \beta_2 \frac{d^2\Delta n}{ds^2} = \Delta C_P(s)$$  \hspace{1cm} (1)

Here, $\Delta n$'s are defined as shape corrections normal to the membrane surface, while the membrane contour-following coordinate is $s$. The ordinary differential equation with constant coefficients (Eq. 1) is analogous to a linear forced spring-damper-mass-spring system where the monotonically increasing time coordinate has been traded for a surface-contour-following coordinate, $s$. Coefficients $\beta_0$, $\beta_1$, and $\beta_2$ are the user-supplied constants that control the rate of convergence of the iterative shape determination process.

Equation (1) is traditionally solved for shape corrections, $\Delta n$, by evaluating its derivatives using finite differencing. The major problem with this approach is its slow convergence in conjunction with the field analysis codes of increasing non-linearity [15]. In an attempt to alleviate these problems, we have developed a new formulation of the elastic membrane design concept, which allows a Fourier series analytical solution to the shape evolution equation [15-18].

Fourier Series Solution of Shape Evolution Equation

It should be noticed that there is an analogy between the forcing function $\Delta C_P(s)$ in the aerodynamic shape design application, which varies arbitrarily with the contour-following coordinate, $s$, and the smelter outer wall surface heat flux difference

$$\Delta q_o = \left(\frac{dT}{dn}\right)_o^\text{measured} - \left(\frac{dT}{dn}\right)_o^\text{computed}$$  \hspace{1cm} (2)

which varies arbitrarily with the circumferential contour-following coordinate, $\theta$. Notice also a global periodicity of the mass-damper-spring forcing function and the outer surface heat flux difference, $\Delta q_o$, that repeats its value at the starting and the ending contour-following $\theta$-coordinate.

Thus, on the inner surface of the furnace wall configuration this elastic membrane surrogate model for inverse shape determination leads to the shape evolution equation [18]

$$\beta_0\Delta n + \beta_1 \frac{d\Delta n}{d\theta} + \beta_2 \frac{d^2\Delta n}{d\theta^2} = \Delta q_o$$  \hspace{1cm} (3)

which has a homogeneous solution of the general form [18]

$$\Delta n_h = Fe^{-\lambda t} + Ge^{-\lambda 2t}$$  \hspace{1cm} (4)
where F and G are (as yet) undetermined coefficients and eigenvalues are determined from

\[
\lambda_{1,2} = -\frac{\beta_1 \pm \sqrt{\beta_1^2 + 4\beta_0\beta_2}}{2\beta_2}
\]

(5)

A particular solution of the elastic membrane model equation (3) can be represented in terms of a Fourier series as

\[
\Delta n_p = A_0 + \sum_{N=1}^{N_{\text{max}}} [A_N \cos N\theta + B_N \sin N\theta]
\]

(6)

The forcing function, \( \Delta q_0 \), can also be represented in terms of another Fourier series as

\[
\Delta q_0 = a_0 + \sum_{N=1}^{N_{\text{max}}} [a_N \cos N\theta + b_N \sin N\theta]
\]

(7)

Then, from (6) it follows that

\[
\frac{d\Delta n_p}{d\theta} = \sum_{N=1}^{N_{\text{max}}} [-A_N N \cos N\theta + B_N N \sin N\theta]
\]

(8)

\[
\frac{d^2\Delta n_p}{d\theta^2} = -\sum_{N=1}^{N_{\text{max}}} [A_N N^2 \cos N\theta + B_N N^2 \sin N\theta]
\]

(9)

Substitution of equations (6), (8) and (9) into the general evolution equation (3) and collection of like terms yields analytical links among the coefficients of the two Fourier series.

\[
A_N = \frac{a_N (N^2\beta_2 - \beta_0) - b_N (\beta_1 N)}{(N^2\beta_2 - \beta_0)^2 + (\beta_1 N)^2}, \quad N = 0, 1, 2, \ldots, N_{\text{max}}
\]

(10)

\[
B_N = \frac{b_N (N^2\beta_2 - \beta_0) + a_N (\beta_1 N)}{(N^2\beta_2 - \beta_0)^2 + (\beta_1 N)^2}, \quad N = 0, 1, 2, \ldots, N_{\text{max}}
\]

(11)

Thus, the complete solution for geometry corrections, \( \Delta n \), in the locally normal direction to the outside surface of the furnace wall can be represented analytically as

\[
\Delta n = Fn^{1/2} + Gn^{1/2} + A_0 + \sum_{N=1}^{N_{\text{max}}}[A_N \cos N\theta + B_N \sin N\theta]
\]

(12)

The unknown constants, F and G, are determined to be zero from the closure conditions \( \Delta n(0) = \Delta n(2\pi) \). This form of the solution of the elastic membrane model equation has significant advantages over the standard finite difference approach since any errors due to finite differencing are removed, because the formulation is exact. Consequently, the Fourier series formulation for the elastic membrane concept in inverse shape determination converges faster than the finite difference formulation [15-18].

**NUMERICAL RESULTS IN HORIZONTAL PLANE**

The Fourier series formulation of the elastic membrane inverse shape determination concept was tested for accuracy and speed of convergence on horizontal cross sections of an idealized furnace, using two simple geometries with outer surface radius \( R_o = 2.0 \) m. The first test geometry had an oval doubly symmetric inner boundary shape given as \( R_1 = 1.0 + 0.5 \sin^2 \theta \) (Figure 1). The second test geometry had only one axis of symmetry with the inner surface represented by a fourth order polynomial where slope was discontinuous at the point \( R_1(0) = R_1(2\pi) \) (Figure 2).

\[
R_1 = 1.0 + 0.5 \left[ \left( \frac{2\pi - \theta}{2\pi} \right)^4 + \frac{\theta}{2\pi} \right]
\]

(13)

Thermal boundary conditions were \( T_i = 2000.0 \) K and \( T_o = 350.0 \) K. For simplicity, the furnace wall was assumed to be made of an isotropic homogeneous material. In principle, the analysis of the steady heat conduction could account for a wall made of a finite number of sub-domains each having a different coefficient of thermal conductivity. This is treated easily by the finite element method and could be treated equally easily by the boundary element method. Even the realistic situation where the local thermal conductivities are temperature-dependent can be treated relatively easily by both numerical methods [1].

We used a highly accurate boundary element heat conduction analysis code [1] to solve Laplace's equation for steady thermal field in the annular region. The entire inverse shape determination procedure consisted of the following steps.

1. The "measured" outer surface heat flux corresponding to the inner surface target shape was determined by solving for the temperature field subject to \( T_i = 2000 \) K and \( T_o = 350 \) K and computing \( dT/dr \) on the outer boundary. These boundary values were considered to be errorless.
2. Then, the inner surface was changed to a guessed shape, which was a unit circle in both test cases.
3. Using the analysis code for heat conduction, steady thermal field was solved in this perfectly circular concentric annular region subject to $T_i = 2000$ K and $T_o = 350$ K.
4. The computed values of $dT/dr$ on the outer boundary were then treated as initial $dT/dr$ computed values.
5. The elastic membrane forcing function, $\Delta q_0$, was then created by the difference between the measured and the initial values of $dT/dr$ on the outer boundary.
6. After several different choices for the values of the elastic membrane coefficients, we used $\beta_0 = 5000.0$, $\beta_1 = 0.0$ and $\beta_2 = 0.0$ that provided the fastest convergence.
7. The inverse design code solved equation (3) for corrections in the wall thickness and updated the shape of the inner surface of the furnace wall as $R_{i, \text{new}} = R_{i, \text{old}} + \Delta R$.
8. This shape was then treated as the new initial shape and the entire procedure was automatically repeated.
9. The difference between the computed and the measured heat flux on the outer surface was used as a convergence indicator, and the shape update process was stopped when the heat flux difference reached an acceptably low value (Figure 3).

The shape of the inner surface of the furnace wall was also used as an indicator of convergence (Figure 4). After ten iterations in the symmetric test case, the RMS error of $dT/dr$ on the outer surface of the furnace wall decreased to 0.2% of its initial value (Figure 5), while the RMS error of the radial location of the inner surface decreased to 1.0% of its initial value (Figure 6).

In the asymmetric geometry test case, the elastic membrane coefficients were chosen as $\beta_0 = 5000.0$, $\beta_1 = 0.0$ and $\beta_2 = 0.0$. After 10 iterations, the external surface heat flux difference practically disappeared (Figure 7) and the inner surface of the furnace wall converged to the target shape (Figure 8). The RMS error of $dT/dr$ on the outer surface of the furnace wall decreased to 0.1% of its initial value (Figure 9), while the RMS error on the inner surface of the furnace wall decreased to 0.8% of its initial value (Figure 10).

Figure 8: Asymmetric case: convergence history of the inner surface geometry.

Figure 6: Symmetric case: convergence history of the RMS error of inner surface geometry.

Figure 9: Asymmetric case: convergence history of the RMS error of the outer surface heat flux.
Effect of Measurement Errors

An actual furnace was not available to evaluate the accuracy of this inverse shape determination method. In actual field operation of the proposed method the thermocouples will read local values of temperature on the outer surface of the furnace wall. These readings will inevitably be in error and this error will be randomly distributed among the thermocouples. It is desirable to get maximum information out of as few thermocouples as possible. Consequently, we simulated measurement of the flux at only eight points on the outer surface of the furnace (Figures 1 and 2). Then, an unbiased error was applied to those eight measurements by using a Gaussian probability distribution.

Values of such randomly perturbed 8 flux values were then spline fitted and interpolated to the remainder of the outer surface of the wall. In a similar fashion the random error was applied to the external temperature thus simulating actual field measurements with errors. Then, the inverse shape determination procedure was performed while measuring the difference between the converged shape subject to such perturbed thermal boundary conditions and the correct shape. The entire process was repeated a number of times (20 in this case) and the average amount of error in the geometry of the predicted inner surface of the furnace wall was determined.

Following are the findings of this exercise in simulating the influence of different levels of measurement errors on the accuracy of the predicted shape of the inner surface of the furnace wall (Table 1). The RMS errors, where the average wall thickness used was 0.75 m, were computed as

$$\Delta R_i = \left( \frac{R_i^{\text{target}} - R_i^{\text{predicted}}}{R_o - R_i} \right)_{\text{average}}$$

NUMERICAL RESULTS IN MERIDIONAL PLANE

In the case when the blast furnace configuration is treated as an axisymmetric shape, only a half of the vertical (meridional) plane needs to be considered (Figures 12 and 13). Using the same elastic membrane concept and the same Fourier series formulation for its analytical solution as it was done in the case of inverse shape determination in the horizontal plane of the furnace was used to determine configuration of the eroded inner surface of the blast furnace wall in the meridional plane.

In this example case, there were two material domains: The hearth bottom 2.5 m of the furnace had thermal conductivity $k = 10.0 \text{ W m}^{-1} \text{ K}^{-1}$. Everything above that line (that is, the side wall) had conductivity $k = 13.0 \text{ W m}^{-1} \text{ K}^{-1}$.

The cold face of the hearth bottom is the furnace bottom surface where natural convective cooling takes place in air with ambient air temperature assumed to be $T_{\text{air}} = 310.0 \text{ K}$ and convective heat transfer was assumed to be $h_{\text{air}} = 30.0 \text{ W m}^{-2} \text{ K}^{-1}$. Temperature probes were assumed located at 40 evenly spaced points on this bottom surface.

The steel shell that contacts the cold face of the hearth side-wall had forced convective cooling by water where the ambient water temperature was assumed to be $T_{\text{water}} = 300.0 \text{ K}$.
and convective heat transfer coefficient was assumed to be $h_{\text{water}} = 150.0 \text{ W m}^2 \text{K}^{-1}$. Temperature probes were assumed to be located at 40 evenly spaced points on this surface as well.

The top boundary was treated as thermally insulated. The left boundary is the furnace vertical symmetry line; thus the boundary condition there was treated as adiabatic.

Curved wall (Figures 12 and 13) is the melt/furnace interface surface, assumed to be maintained at a constant temperature of $T_{\text{inner}} = 1720.0 \text{ K}$.

Here, we used a fast and accurate finite element method [22] to analyze steady temperature field in the smelter wall. Forcing function in Eq. 3 was the difference between measured temperatures on vertical side-wall and on the bottom wall and FEM calculated temperatures on these walls. In actual applications, the measured surface temperatures and heat fluxes would be provided at a relatively small number of locations and then interpolated at the larger number (in this example 80) surface grid points by using, for example, B-splines.

Inner surface shape corrections were performed along the rays emanating from the imaginary point where the top boundary and furnace centerline intersect. Boundary conditions on Eq. 3 were set such that $\partial \Delta \eta / \partial s = 0$ at the endpoints so that shape deformation is described with a Fourier cosine series. User-specified coefficients in Eq. 3 were: $\beta_0 = 200.0$; $\beta_1 = 0.0$; $\beta_2 = -1.0$ leading to fast and accurate results (Figures 12-16).

Shape error was calculated at 80 evenly spaced points on the design surface (melt-refractory interface) by finding the minimum distances between these points and the target contour (considered to be made up of line segments). RMS and Max values are based on that set of 80 individual shape error values.

Temperature errors (Figure 16) were calculated at each of the 40 evenly-spaced points on the vertical side-wall and 40 evenly-spaced points on the bottom, as $\text{Err} = \left| T_{\text{calculated}} - T_{\text{measured}} \right|$. RMS and Max values were based on that set of 80 individual error values.
